PRODUCT INFORMATION

ESMERON® (Rocuronium bromide)

NAME OF THE MEDICINE

Rocuronium bromide, 1-(17β-Acetoxy-3α-hydroxy-2 β-morpholino-5α-androstan-16β-y1)-1-
allylpyrrolidinium bromide; C_{32}H_{53}BrN_{2}O_{4}

CAS Number 119302-91-9

DESCRIPTION

Rocuronium bromide is a quaternary aminosteroid and an analogue of vecuronium bromide. It is
an off-white to pale yellow or slightly pink amorphous powder which is readily soluble in water
(>200mg/mL). A 1% w/v solution in water has a pH of 8.9 -9.5. In aqueous solution rocuronium
bromide is more stable at acidic pH.

Esmeron 25mg = 2.5mL, Esmeron 50mg = 5mL and Esmeron 100mg = 10mL contain
rocuronium bromide 10mg/mL, sodium acetate, sodium chloride, acetic acid and water for
injections in a clear, colourless to faintly yellow solution with a pH of 3.8 - 4.2. Rocuronium
bromide is administered by intravenous bolus or infusion.

PHARMACOLOGY

Pharmacodynamics

Rocuronium is a fast onset (relative to vecuronium), intermediate acting non-depolarising
neuromuscular blocking agent. It acts by competing with the natural transmitter acetylcholine and
blocking the cholinceptors located at the motor end-plate of the striated muscle. This is unlike
suxamethonium which causes depolarisation and renders the end-plate, after initial contraction,
unresponsive to stimuli, thus producing paralysis of the striated muscle. The action of
rocuronium is antagonised by acetylcholinesterase inhibitors such as neostigmine, edrophonium
and pyridostigmine. The neuromuscular block can also be reversed by sugammadex, a Selective
Relaxant Binding Agent. Rocuronium does not produce clinically significant autonomic and
cardiovascular effects within the recommended dose range and is not expected to modulate
cardiovascular effects of anaesthetics or other drugs used during surgery.

The ED90 (dose required to produce 90% depression of the twitch response of the thumb to
stimulation of the ulnar nerve) during balanced anaesthesia is approximately 0.3mg.kg^{-1}
rocuronium bromide. The ED95 in infants is lower than in adults and children (0.25, 0.35 and 0.40 mg.kg\(^{-1}\), respectively).

The mean pharmacodynamic parameter values for rocuronium over a range of doses are presented in Tables 1 and 2.

*Clinical duration = duration until spontaneous recovery to 25% of control twitch height.

The clinical duration (the duration until spontaneous recovery to 25% of control twitch height) with 0.6 mg.kg\(^{-1}\) rocuronium bromide is 30 - 40 minutes. The total duration (time until spontaneous recovery to 90% of control twitch height) is 50 minutes. The mean time of spontaneous recovery of twitch response from 25 to 75% (recovery index) after a bolus dose of 0.6mg.kg\(^{-1}\) rocuronium bromide is 14 minutes.

With lower doses of 0.3 to 0.45mg.kg\(^{-1}\) rocuronium bromide (1 - 1.5 x ED90), onset of action is slower and duration of action is shorter. With high doses of 2mg.kg\(^{-1}\), clinical duration is 110 minutes.
Intubation during routine anaesthesia
Within 60 seconds following intravenous administration of a dose of 0.6 mg.kg\(^{-1}\) rocuronium bromide (2 x ED\(_{90}\) under intravenous anaesthesia), adequate intubation conditions can be achieved in nearly all patients of which in 80% intubation conditions are rated excellent. General muscle paralysis for any type of procedure is established within 2 minutes. After administration of 0.45 mg.kg\(^{-1}\) rocuronium bromide, acceptable conditions are present after 90 seconds.

Rapid Sequence Induction
During rapid sequence induction of anaesthesia under propofol or fentanyl/thiopental anaesthesia, adequate intubation conditions are achieved within 60 seconds in 93% and 96% of the patients, respectively, following a dose of 1.0 mg.kg\(^{-1}\) rocuronium bromide. The rate of excellent intubations after a 1.0 mg.kg\(^{-1}\) rocuronium dose was achieved in 66% and 65% of the patients, respectively. The clinical duration with this dose approaches 1 hour, at which time the neuromuscular block can be safely reversed. Following a dose of 0.6 mg.kg\(^{-1}\) rocuronium bromide, adequate intubation conditions are achieved within 60 seconds in 81% and 75% of the patients during a rapid sequence induction technique with propofol and fentanyl/thiopental, respectively.

Special populations
Mean onset time in infants and children at an intubation dose of 0.6 mg.kg\(^{-1}\) is slightly shorter than in adults. The duration of relaxation and the time to recovery tend to be shorter in children compared to infants and adults.

The duration of action of maintenance doses of 0.15mg.kg\(^{-1}\) rocuronium bromide might be somewhat longer under enflurane and isoflurane anaesthesia and in patients with hepatic disease (approximately 20 minutes) than in patients without impairment of excretory organ functions under intravenous anaesthesia (approximately 13 minutes). No accumulation of effect (progressive increase in duration of action) with repetitive dosing at the recommended level has been observed.

Intensive Care Unit
Following continuous infusion in the Intensive Care Unit, the time to recovery of the train of four ratio to 0.7 depends on the level of block at the end of the infusion. After a continuous infusion for 20 hours or more the median (range) time between return of T\(_2\) to train of four stimulation and recovery of the train of four ratio to 0.7 approximates 1.5 (1-5) hours in patients without multiple organ failure and 4 (1-25) hours in patients with multiple organ failure.

Cardiovascular surgery
In patients scheduled for cardiovascular surgery the most common cardiovascular changes during the onset of maximum block following 0.6 - 0.9 mg.kg\(^{-1}\) rocuronium bromide are a slight and clinically insignificant increase in heart rate up to 9% and an increase in mean arterial blood pressure up to 16% from the control values.

Reversal of muscle relaxation
The action of rocuronium can be antagonised either by sugammadex or by acetylcholinesterase inhibitors (neostigmine, pyridostigmine or edrophonium). Sugammadex can be given for routine reversal (at 1-2 post-tetanic counts to reappearance of T\(_2\)) or immediate reversal (3 minutes after rocuronium bromide administration). Acetylcholinesterase inhibitors can be administered in appropriate dosage, at reappearance of T\(_2\) or at the first signs of clinical recovery.
Pharmacokinetics

After intravenous administration of a single bolus dose of rocuronium bromide the plasma concentration time course runs in three exponential phases. In normal adults, the mean (95% CI) elimination half-life is 73 (66-80) minutes, the (apparent) volume of distribution at steady state conditions is 203 (193-214) mL/kg and plasma clearance is 3.7 (3.5 - 3.9) mL/ kg/ min.

Rocuronium is excreted in urine and bile. Excretion in urine approaches 40% within 12-24 hours. After injection of a radiolabeled dose of rocuronium bromide, excretion of the radiolabel is on average 47% in urine and 43% in faeces after 9 days. Approximately 50% is recovered as the parent compound.

In infants (3 months to 1 year), the apparent volume of distribution at steady state conditions is increased compared to adults and children (1-8 years). In older children (3-8 years), a trend is seen toward higher clearance and shorter elimination half-life compared to adults, younger children and infants. The mean (± SD) elimination half-life in older children (3-8 years), adults, younger children (1-3 years) and infants (3-12 months) is respectively 48 (±18), 73 (±32), 65 (±39) and 79 (±30) minutes.

Geriatric patients and patients with hepatic and/or biliary tract disease and/or renal failure

In controlled studies in geriatric patients and in patients with renal dysfunction, the plasma clearance was reduced. In most studies, however, this reduction was not statistically significant. In patients with hepatic disease, the mean elimination half-life is prolonged by 30 minutes and the mean plasma clearance is reduced by 1.0 mL/kg/min. See also Dosage and Administration.

Intensive Care Unit

When administered as a continuous infusion to facilitate mechanical ventilation for 20 hours or more, the mean elimination half-life and the mean (apparent) volume of distribution at steady state are increased. A large between patient variability is found in controlled clinical studies, related to nature and extent of (multiple) organ failure and individual patient characteristics. In patients with multiple organ failure a mean (± SD) elimination half-life of 21.5 (± 3.3) hours, a (apparent) volume of distribution at steady state of 1500 (± 800) mL/kg and a plasma clearance of 2.1 (± 0.8) mL/kg/min were found.

There is no proper animal model to mimic the usually extremely complex clinical situation of the ICU patient. Therefore the safety of Esmeron when used to facilitate mechanical ventilation in the Intensive Care Unit is mainly based on the results obtained in clinical studies.

CLINICAL TRIALS

The use of rocuronium bromide during rapid sequence induction of anaesthesia was studied in two pivotal studies, including a total of 681 adult and geriatric patients, one using 3-5 mg/kg thiopentone (plus fentanyl) as the induction agent, and the other using 2.5 mg/kg propofol. The studies included three study groups: 0.6 mg/kg rocuronium, 1.0 mg/kg rocuronium and 1.0 mg/kg suxamethonium. The patients were intubated within 60 seconds after the end of muscle relaxant administration. In the first part of both studies, intubation conditions after 0.6 mg/kg and 1.0 mg/kg rocuronium bromide were compared. In the second part of both studies, the optimal rocuronium dose was compared with 1.0 mg/kg suxamethonium. The optimal rocuronium dose (i.e. 1.0 mg/kg in both studies) and 1.0 mg/kg suxamethonium were considered to be clinically equivalent if a difference of less than 10% in the number of clinically acceptable intubating conditions was demonstrated. Based on this assumption a 13% rate of clinically unacceptable intubating conditions would have been acceptable. In the first part of both studies, it was
demonstrated that the frequency of excellent intubating conditions was higher after a 1.0 mg/kg rocuronium dose than after the 0.6 mg/kg dose (65% versus 28% in the thiopentone study and 66% versus 40% in the propofol study). The percentage of clinically acceptable intubating conditions is comparable for 1.0 mg/kg rocuronium compared to 1.0 mg/kg suxamethonium although rocuronium resulted less frequently in excellent intubating conditions (65% versus 80% in the thiopentone study and 66% versus 74% in the propofol study, although statistical significance was not reached in the latter study). In the thiopentone study, intubation could not be performed in 2% of the patients in the 0.6 mg/kg rocuronium group and in 1% of the patients in the 1.0 mg/kg rocuronium group 60 seconds after administration of the muscle relaxant. Intubation could be performed in all patients receiving 1.0 mg/kg suxamethonium. In the propofol study, intubation could not be performed in 1% of the patients in the 1.0 mg/kg rocuronium group and in 1% of the patients in the 1.0 mg/kg suxamethonium group but in all patients in the 0.6 mg/kg rocuronium group. These studies do not provide information on the relative time to onset of suxamethonium vs rocuronium bromide as the protocols specified assessment of intubation conditions at 60 seconds.

The use of rocuronium bromide in the Intensive Care Unit to facilitate mechanical ventilation was studied in two pivotal studies, including a total of 95 adult patients; 35 of the 95 patients (37%) had received rocuronium bromide for at least 2 days, and 11 (12%) for 4 days. Both patients with and without multiple organ failure were included. In both studies, rocuronium bromide administration started with a large loading bolus of 0.6 mg/kg and upon reappearance of one or two responses to TOF stimulation, a rocuronium bromide infusion was started for as long as required up to a maximum of seven days.

There are no data to support ICU use in infants, children, elderly (>70 years old), those with burns and pre-existing myopathy.

**INDICATIONS**
Rocuronium is indicated as an adjunct to general anaesthesia to facilitate endotracheal intubation during routine induction, to provide muscle relaxation and to facilitate mechanical ventilation in adults, children and infants over 1 month of age.

Rocuronium is also indicated as an adjunct to general anaesthesia to facilitate endotracheal intubation during rapid sequence induction when suxamethonium is contraindicated, however, this has not been studied in infants and children.

Rocuronium is also indicated as an adjunct in the intensive care unit (ICU) to facilitate mechanical ventilation.

**CONTRAINDICATIONS**
Hypersensitivity reactions to rocuronium or the bromide ion or to any of the excipients.

**PRECAUTIONS**
Particularly in the case of former anaphylactic reactions, rocuronium bromide should be administered only under the supervision of an experienced clinician.

Since rocuronium causes paralysis of the respiratory muscles, ventilatory support is mandatory for patients treated with this drug. Ventilation should be continued until adequate spontaneous respiration is restored. As with all neuromuscular blocking agents, it is important to anticipate intubation difficulties, particularly when used as part of a rapid sequence induction technique. In
case of intubation difficulties resulting in a clinical need for immediate reversal of a rocuronium induced neuromuscular block, the use of sugammadex should be considered.

As with other neuromuscular blocking agents, residual curarization has been reported for Esmeron. Factors which could cause residual curarization after extubation in the post-operative phase (such as drug interactions or patient condition) should also be considered. If not already used as part of usual clinical practice, the use of sugammadex or another reversal agent should be considered, especially in those cases where residual curarization is more likely to occur.

Anaphylactic reactions can occur following administration of neuromuscular blocking agents. Precautions for treating such reactions should always be taken. Allergic cross-reactivity between muscle relaxants has been reported.

In general, following long term use of neuromuscular blocking agents in the ICU, prolonged paralysis and/or skeletal muscle weakness has been noted. In order to help preclude possible prolongation of neuromuscular block and/or overdosage it is strongly recommended that neuromuscular transmission is monitored throughout the use of neuromuscular blocking agents. In addition, patients should receive adequate analgesia and sedation. Furthermore, neuromuscular blocking agents should be titrated to effect in the individual patients by or under supervision of experienced clinicians who are familiar with their actions and with appropriate neuromuscular monitoring techniques.

Myopathy after long term administration of other non-depolarizing neuromuscular blocking agents in the ICU in combination with corticosteroid therapy has been reported regularly. Therefore the period of use of the neuromuscular blocking agent should be limited as much as possible in patients receiving both neuromuscular blocking agents and corticosteroids.

If suxamethonium is used for intubation, the administration of Esmeron should be delayed until the patient has clinically recovered from the neuromuscular block induced by suxamethonium.

Doses of rocuronium bromide greater than 0.9mg/kg may increase the heart rate; this effect could counteract the bradycardia produced by other anaesthetic agents or by vagal stimulation.

Prolonged use (> 48 hours) of non-depolarising muscle relaxants in the ICU should be avoided (See also Dosage and Administration).

Patients with multiple organ failure require lower infusion rates (See also Dosage and Administration).

The following conditions may influence the pharmacokinetics and/or pharmacodynamics of rocuronium. A peripheral nerve stimulator may be of use in monitoring the neuromuscular response in patients presenting with such complications.

Infants (one month to twelve months of age): Mean onset time in infants and children at an intubation dose of 0.6 mg.kg⁻¹ is slightly shorter than in adults. The duration of relaxation and the time to recovery tend to be shorter in children compared to infants and adults.

In one study the clinical duration of action was 43 minutes in infants compared with 26 minutes in children aged 3 to 8 years. In a second study two of twenty subjects exhibited a prolonged
duration of response and another two subjects appeared to be resistant to reversal of effects with neostigmine.

**Hepatic and/or biliary tract disease and renal failure:** Because rocuronium is excreted in urine and bile, it should be used with caution in patients with clinically significant hepatic and/or biliary diseases and/or renal failure. In these patient groups prolongation of action has been observed with doses of 0.6 mg.kg⁻¹ rocuronium bromide. It is recommended the infusion rate is titrated to effect.

**Prolonged Circulation Time:** Conditions associated with prolonged circulation time such as cardiovascular disease, old age and oedematous state resulting in an increased volume of distribution may contribute to a slower onset of action of rocuronium. The duration of action may also be prolonged due to a reduced plasma clearance.

**Neuromuscular Disease:** Like other neuromuscular blocking agents, rocuronium bromide should be used with extreme caution in patients with neuromuscular disease or after poliomyelitis since the response to neuromuscular blocking agents may be considerably altered in these cases. The magnitude and direction of this alteration may vary widely. In patients with myasthenia gravis or with the myasthenic (Eaton-Lambert) syndrome, small doses of rocuronium bromide may have profound effects and rocuronium bromide should be titrated to the response.

**Hypothermia:** In surgery under hypothermic conditions, the neuromuscular blocking effect of rocuronium is increased and the duration prolonged.

**Obesity:** Like other neuromuscular blocking agents, rocuronium may exhibit a prolonged duration of action and a prolonged spontaneous recovery in obese patients, when the administered doses are calculated on actual body weight.

**Burns:** Patients with burns are known to develop resistance to non-depolarising neuromuscular blocking agents. It is recommended that the dose is titrated to response.

**Conditions which may increase the effects of Esmeron:** Hypokalemia (e.g. after severe vomiting, diarrhoea and diuretic therapy), hypocalcemia (after massive transfusion), hypermagnesemia, hypoproteinemia, dehydration, acidosis, hypercapnia and cachexia may all increase the effects of rocuronium. Severe electrolyte disturbances, altered blood pH and dehydration should therefore be corrected prior to surgery whenever possible.

**Carcinogenesis, Mutagenesis and Impairment of Fertility:** Carcinogenicity and fertility studies with rocuronium bromide have not been conducted. Rocuronium bromide showed no genotoxic potential in standard assays of gene mutation and chromosomal damage.

**Use in Pregnancy** (Category B2).
Rocuronium bromide was not embryotoxic and/or teratogenic when administered to rats during pregnancy (day-6 to day-17) at IV neuromuscular blocking doses of 0.3mg/kg. There are no adequate and well-controlled studies in pregnant women. Esmeron should be used in pregnancy only if the potential benefits justify the potential risk to the foetus.
In patients receiving magnesium sulphate for toxaemia the dose of rocuronium bromide should be reduced and carefully titrated to twitch response.
Use in Lactation
Insignificant levels of rocuronium were found in the milk of lactating rats, however there are no data on the use of rocuronium bromide in lactating women. Rocuronium bromide should only be given to lactating women when the attending physician decides that the benefits outweigh the risks.

Effects on ability to drive and use machinery
Since Esmeron is used as an adjunct to general anaesthesia, the usual precautionary measures after a general anaesthetic should be taken for ambulatory patients.

Interactions with other drugs
Coadministration of the following compounds has been shown to influence the magnitude and/or the duration of action of non-depolarising neuromuscular blocking agents.

Effect of other drugs on Esmeron

Increased effect
- Halogenated volatile anaesthetics potentiate the neuromuscular block of Esmeron. The effect only becomes apparent with maintenance dosing (see Dosage and Administration). With the presence of these volatile agents reversal of the block with anticholinesterase inhibitors could also be inhibited.
- After intubation with suxamethonium (see Dosage and Administration).
- Long-term concomitant use of corticosteroids and Esmeron in the ICU may result in prolonged duration of neuromuscular block or myopathy (see Precautions and Adverse reactions).

Other drugs:
- Antibiotics: aminoglycoside, lincosamide and polypeptide antibiotics, acylamino-penicillin antibiotics
- Diuretics, quinidine and its isomer quinine, magnesium salts, calcium channel blocking agents, lithium salts, local anaesthetics (lignocaine I.V., bupivacaine epidural) and acute administration of phenytoin or β-blocking agents.

Recurarization has been reported after post-operative administration of:
aminoglycoside, lincosamide, polypeptide and acylamino-penicillin antibiotics, quinidine, quinine and magnesium salts (see Precautions).

Decreased effect:
- prior chronic administration of corticosteroids, phenytoin or carbamazepine.

Variable effect:
- Administration of other non-depolarising neuromuscular blocking agents in combination with Esmeron may produce potentiation or attenuation of the neuromuscular block, depending on the order of administration and the neuromuscular blocking agent used.
- Suxamethonium given after the administration of a non-depolarising neuromuscular blocking agent may produce potentiation or attenuation of the neuromuscular blocking effect of the non-depolarising neuromuscular blocking agent.
Effect of Esmeron on other drugs
Esmeron combined with lignocaine may result in a quicker onset of action of lignocaine.

ADVERSE REACTIONS
The most commonly occurring adverse drug reactions include injection site pain/reaction, changes in vital signs and prolonged neuromuscular block. The most frequently reported serious adverse drug reactions during post-marketing surveillance is “anaphylactic and anaphylactoid reactions” and associated symptoms. See also the explanations below the table.

<sup>a</sup> Frequencies are estimates derived from post-marketing surveillance reports and data from the general literature.
<sup>b</sup> Post marketing surveillance data cannot give precise incidence figures. For that reason, the reporting frequency was divided over two rather than five categories.
<sup>c</sup> After long term use in the ICU.
Anaphylaxis
Although very rare, severe anaphylactic reactions to neuromuscular blocking agents, including Esmeron, have been reported. Anaphylactic/anaphylactoid reactions are: bronchospasm, cardiovascular changes (e.g. hypotension, tachycardia, circulatory collapse – shock), and cutaneous changes (e.g. angioedema, urticaria). These reactions have, in some cases, been fatal.

Since neuromuscular blocking agents are known to be capable of inducing histamine release both locally and systemically, the possible occurrence of itching or erythematous reactions at the site of injection and/or generalised histaminoid (anaphylactoid) reactions (see also under anaphylactic reactions above) should always be considered when administering these drugs.

In clinical studies only a slight increase in mean plasma histamine levels has been observed following rapid bolus administration of 0.3-0.9 mg .kg⁻¹rocuronium bromide.

Local injection site reactions
During rapid sequence induction of anaesthesia, pain on injection has been reported, especially when the patient has not yet completely lost consciousness and particularly when propofol is used as the induction agent. In clinical studies, pain on injection has been noted in 16% of the patients who underwent rapid sequence induction of anaesthesia with propofol and in less than 5% of the patients who underwent rapid sequence induction of anaesthesia with fentanyl and thiopental.

Prolonged neuromuscular block
The most frequent adverse reaction to nondepolarising blocking agents as a class consists of an extension of the drug’s pharmacological action beyond the time period needed. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle paralysis resulting in respiratory insufficiency or apnea.

ICU myopathy
Myopathy has been reported after the use of various neuromuscular blocking agents in the ICU in combination with corticosteroids (see Precautions).

Rapid Sequence Induction Clinical Trial Data:
The percentage of patients with at least one adverse event, with causality related to the study drug, is tabulated below for the all-patients-treated groups of both pivotal studies. It includes all adverse events reported with an incidence of 1% or greater. A dash represents an incidence of less than 1%.

**DOSAGE AND ADMINISTRATION**

Like other neuromuscular blocking agents, Esmeron should only be administered by, or under supervision of, experienced clinicians who are familiar with the action and use of these drugs.

The product is for single patient use and contains no antimicrobial agent.

As with other neuromuscular blocking agents, the dosage of rocuronium bromide should be individualised in each patient. The anaesthetic method used, the duration of surgery, the method of sedation and the expected duration of mechanical ventilation, the possible interaction with other drugs that are administered concomitantly, and the condition of the patient should be taken into account when determining the dose. The use of an appropriate neuromuscular monitoring technique is recommended for evaluation of the neuromuscular block and the recovery.

Inhalation anaesthetics do potentiate the activity of rocuronium. This potentiation, however becomes clinically relevant in the course of anaesthesia, when the volatile agents have reached the tissue concentrations required for this interaction. Consequently, adjustments with rocuronium bromide should be made by administering smaller maintenance doses at less frequent intervals or by using lower infusion rates of rocuronium bromide during long lasting procedures (longer than one hour) under inhalational anaesthesia (see Interactions with other Drugs).

In adult patients the following dosage recommendations may serve as a general guideline for tracheal intubation and muscle relaxation for short to long lasting surgical procedures and for use in the intensive care unit. Elderly patients (65 - 80 years) manifest similar sensitivity to rocuronium as younger adults.
**Surgical Procedures**

**Tracheal intubation:** The standard intubating dose during routine anaesthesia is 0.6 mg.kg\(^{-1}\) rocuronium bromide. This dose can also be used for facilitating intubation during rapid sequence induction of anaesthesia. However, as part of a rapid sequence induction technique, a dose of 1.0 mg.kg\(^{-1}\) rocuronium bromide is recommended.

Higher doses: Should there be a reason for selection of larger doses in individual patients, initial doses up to 2 mg.kg\(^{-1}\)rocuronium bromide have been administered during surgery without adverse cardiovascular effects being noted. The use of these high dosages of rocuronium decreases the onset time and increases the duration of action (see Pharmacodynamics).

**Maintenance Dose:** 0.15 mg.kg\(^{-1}\) rocuronium bromide; in the case of long-term inhalational anaesthesia, this should be reduced to 0.075-0.1 mg.kg\(^{-1}\) rocuronium bromide. The maintenance doses should best be given when twitch height has recovered to 25% of control twitch height, or when 2 to 3 responses to train of four stimulation are present.

**Continuous Infusion:** A loading dose of 0.6mg/kg is recommended. When neuromuscular block starts to recover the infusion should be started and the rate adjusted to maintain twitch response at 10% of control twitch height or to maintain 1 to 2 responses to train of four stimulation.

In adults under intravenous anaesthesia, the infusion rate required to maintain neuromuscular block at this level ranges from 0.3-0.6 mg/kg/h and under inhalational anaesthesia, the infusion rate ranges from 0.3-0.4 mg/kg/h. Continuous monitoring of the degree of blockade is recommended since infusion rate requirements vary from patient to patient and with the anaesthetic method used. A reduction in infusion rate may be required in patients with significant renal and/or hepatic disease.

**Paediatric patients:** For infants (28 days-23 months), children (2-11 years) and adolescents (12-18 years) the recommended intubation dose during routine anaesthesia and maintenance dose are similar to those in adults.

For continuous infusion in paediatrics, the infusion rates, with exception of children, are the same as for adults. For children higher infusion rates might be necessary. For children the same initial infusion rates as for adults are recommended and this should be adjusted to maintain twitch response at 10% of control twitch height or to maintain 1 or 2 responses to train of four stimulation during the procedure.

During continuous infusion in paediatric patients, dose and infusion rate must be carefully monitored and adjusted if necessary to allow for age-related differences in pharmacokinetics. There are no data to support recommendations for the use of rocuronium bromide in neonates (0-1 month).

The experience with rocuronium bromide in rapid sequence induction in paediatric patients is limited. Rocuronium bromide is therefore not recommended for facilitating tracheal intubation conditions during rapid sequence induction in paediatric patients.

**Dosing in geriatric patients and patients with hepatobiliary disease and/or renal failure:** The intubation dose for geriatric patients and patients with hepatic and/or biliary tract disease and/or renal failure is 0.6 mg.kg\(^{-1}\) rocuronium bromide. Regardless of the anaesthetic technique used,
the recommended maintenance dose for these patients is 0.075-0.1 mg.kg\(^{-1}\) rocuronium bromide, and the recommended infusion rate is 0.3-0.4 mg/kg/h (see also Continuous Infusion).

**Overweight and obese patients:** Doses should be adjusted to conform with lean body mass in patients with a weight more than 30% higher than ideal body weight.

**Intensive Care Procedures**

**Tracheal intubation**

For tracheal intubation, the same dose should be used as described above under surgical procedures.

**Maintenance dosing:** The use of an initial loading dose of 0.6mg rocuronium bromide per kg body weight is recommended, followed by a continuous infusion as soon as twitch height recovers to 10% or upon reappearance of 1 to 2 twitches to train of four stimulation. Dosage should always be titrated to effect in the individual patient. The recommended initial infusion rate for the maintenance of a neuromuscular block of 80-90% (1 to 2 twitches to TOF stimulation) in adult patients is 0.3 – 0.6 mg/kg/h during the first hour of administration, which will need to be decreased during the following 6-12 hours, according to the individual response. Thereafter, individual dose requirements remain relatively constant.

A large between patient variability in hourly infusion rates has been found in controlled studies, with mean hourly infusion rates ranging from 0.2-0.5 mg/kg/h depending on nature and extent of organ failure(s), concomitant medication and individual patient characteristics. To provide optimal individual patient control, monitoring of neuromuscular transmission is strongly recommended. Administration up to 7 days has been investigated. There are no data to support dose recommendations for the facilitation of mechanical ventilation in paediatric and geriatric patients.

Patients with multiple organ failure require lower infusion rates (See also PRECAUTIONS).

Prolonged use (> 48 hours) of non-depolarising muscle relaxants in the ICU should be avoided. (See also PRECAUTIONS).

**Physical Compatibilities:**

Compatibility studies with the following infusion fluids have been performed. In nominal concentrations of 0.5 mg/mL and 2.0 mg/mL Esmeron has been shown to be compatible with: 0.9% NaCl, 5% glucose, 5% glucose in saline, sterile water for injections, Compound Sodium Lactate and Haemaccel. Administration should be begun immediately after mixing, and should be completed within 24 hours. Unused solutions should be discarded.

Prior to use, prepared infusions and syringes after withdrawal of the product from the vial, should be stored at 2°C-8°C and used as soon as practicable after preparation. Any unused solution and product withdrawn into a syringe should be discarded after 24 hours.

If multiple use in one patient is intended, product withdrawn into a syringe should be used within 6 hours of the initial dose, and any remainder discarded.

Those drugs for which incompatibilities have been demonstrated are listed below.
**Physical Incompatibilities:**
Physical incompatibility has been documented when Esmeron is added to solutions containing amoxyccillin, amphotericin, azathioprine, cephalixin, cloxacillin, dexamethasone, diazepam, erythromycin, famotidine, frusemide, hydrocortisone sodium succinate, insulin, Intralipid, methylprednisolone, prednisolone sodium succinate, thiopentone sodium, trimethoprim and vancomycin hydrochloride.

Esmeron must not be mixed with other solutions or drugs except those mentioned above (see Physical Compatibilities).

If Esmeron is administered via the same infusion line that is also used for other drugs, it is important that this infusion line is adequately flushed (e.g. with 0.9 % NaCl) between administration of Esmeron and drugs for which incompatibility with Esmeron has been demonstrated or for which compatibility with Esmeron has not been established.

**OVERDOSE**
The symptoms of overdosage with a non-depolarising muscle relaxant are those of prolonged paralysis, apnoea, low tidal volume, respiratory depression and/or persistent muscle weakness. In animal studies, severe depression of cardiovascular function ultimately leading to cardiac collapse did not occur until a cumulative dose of 750 x ED90 (135mg.kg⁻¹ rocuronium bromide) was administered.

In the event of overdosage and prolonged neuromuscular block, the patient should continue to receive ventilatory support and sedation. In this situation there are two options for the reversal of neuromuscular block: (1) Sugammadex can be used for reversal of intense (profound) and deep block. The dose of sugammadex to be administered depends on the level of neuromuscular block. (2) An acetylcholinesterase inhibitor (e.g. neostigmine, edrophonium, pyridostigmine), with appropriate vagolytic (e.g atropine) can be used at reappearance of T₂ or at the first signs of clinical recovery and should be administered in adequate doses. If administration of an acetylcholinesterase inhibiting agent fails to reverse the effects of rocuronium, ventilation must be continued until spontaneous breathing is restored.

Use of a reversal agent should not begin until definite signs of spontaneous recovery are present. Overdosage of an acetylcholinesterase inhibitor can be dangerous.

**PRESENTATION**
Esmeron 25mg = 2.5mL – pack of 10 glass vials in an outer cardboard box. AUST R 80338*
Esmeron 50mg = 5mL - pack of 10 glass vials in an outer cardboard box. AUST R 57063
Esmeron 100mg = 10mL - pack of 10 glass vials in an outer cardboard box. AUST R 57064

The rubber stopper in the vial does not contain latex.

**STORAGE**
Store at 2°C-8°C until the expiry date indicated on the label (exp:….). Esmeron is intended to be used for one dose and in one patient only. Unused solutions should be discarded. Esmeron should not be returned to 2°C-8°C storage after it has been kept outside the refrigerator 8-30°C (normal use in the anaesthetic room or operating theatre). The date of removal should be noted on the vial and the product discarded if not used in 12 weeks.
